On the usage of the Singular Spectrum Analysis for precision estimation and editing of total atmospheric delay time series

M. S. Vasiuta[*], *V. Ya. Choliy*

Taras Shevchenko National University of Kyiv, 64/13 Volodymyrska St., 01601, Kyiv, Ukraine

We use Singular Spectrum Analysis (**SSA**) for precision estimation of time series of total zenith atmospheric delay for a list of European GNSS data stations proceed in Main Astronomical Observatory GNSS processing centre. The series are downloadable at `ftp://ftp.mao.kiev.ua/pub/gnss/products/IGS05/`. Analysis of the principal components of the series allowed us to clean the series by removing noise out of them. With the capabilities of SSA some gaps in the data were filled out.

Key words: meteorology and atmospheric dynamics, instruments and techniques

INTRODUCTION

Singular Spectrum Analysis (SSA) and its two-dimensional extension (2dSSA) are frequently used in time series analysis. Authors' experience along with some useful references were presented in [3, 4]. Here we investigate one promising feature of SSA: its forecasting capabilities. There are two variants of forecasts with SSA, but here we use linear recurrent formula (LRF). Our purpose is to fill the gaps in time series of total atmospheric delay keeping the statistical properties of the series. As a byproduct the estimation of noise part of the series will be made using Principal Component Analysis (PCA) as a key step of SSA.

Let us outline here the properties of LRF. The explanation of the SSA itself can be found in [1, 2].

Given: $X_N = (x_1, x_2, \dots, x_N), N > 2$ — the initial series, $L : 1 < L < N$ — window length; $L^r \subset R^L, r < L$ — some linear space. Given: ort vector $e_L = (0, 0, \dots, 1) \in R^L, \notin L^r$. M is an amount of the forecasted points to be found.

There is the algorithm for recurrent forecast:

1. $\mathbb{X} = (\mathbf{X}_1 : \mathbf{X}_2 : \cdots : \mathbf{X}_K), \quad K = N - L + 1$ is trajectory matrix for X_N;
2. $\mathbf{P}_1$, where $\mathbf{P}_r$ is ortonormalised basis L_r;
3. $\hat{\mathbb{X}} = (\hat{\mathbb{X}}_1 : \hat{\mathbb{X}}_2 : \cdots : \hat{\mathbb{X}}_K) = \sum_{i=1}^{r} \mathbf{P}_i \mathbf{P}_i^T \cdot \mathbb{X}$ is ortogonal projection of the vectors $\hat{\mathbf{X}}_i$ on L_r;
4. $\tilde{\mathbb{X}} = (\tilde{\mathbf{X}}_1 : \tilde{\mathbf{X}}_2 : \cdots : \tilde{\mathbf{X}}_K)$ is hankelised matrix $\hat{\mathbb{X}}$. Then $\tilde{\mathbb{X}}$ is trajectory matrix of some series $\tilde{X}_N = (\tilde{x}_1, \tilde{x}_2, \dots, \tilde{x}_N)$;
5. $\forall\ \mathbf{Y} \in R^L$ sign as $\mathbf{Y}_\triangle$, which is the vector consisted of its last $(L-1)$ components, and $\mathbf{Y}^\triangledown$ consisted of its first $(L-1)$ components;
6. $\nu^2 = \pi_1^2 + \pi_2^2 + \cdots + \pi_r^2$, where π_i is latter component of the vector $\mathbf{P}_i$.

It might be shown that the last component of any vector $\mathbf{Y} = (y_1, y_2, \dots, y_L)^T \in L_r$ is a linear combination of its first components:

$$y_L = a_1 y_{L-1} + a_2 y_{L-2} + \cdots + a_{L-1} y_1,$$

and parameters' vector is:

$$\mathbf{R} = (a_{L-1}, a_{L-2}, \dots, a_2, a_1)^T = \frac{1}{1-\nu^2} \sum_{i=1}^{r} \pi_i \mathbf{P}_i^\triangledown,$$

and it does not depend on the preselected basis. Recurrently forecasted series $G_{N+M} = (g_1, g_2, \dots, g_{N+M})$ can be build by recurrently extended initial series:

$$g_i = \begin{cases} \tilde{x}_i, & i = 1, N, \\ \sum\limits_{j=1}^{L-1} a_j g_{i-j}, & i = N+1, N+M. \end{cases}$$

MODEL

Editable time series are represented as tropospheric total delay values with one hour step (here and below designated as TROTOT). Producing of the series is a part of activities of Main Astronomical Observatory GNSS processing centre [5]. For further processing the arithmetic mean in all series were removed according to requirements of the SSA. Window size was preselected equal to one solar day, i. e $L = 24$ is the least obvious period of the series.

[*] ecratos12@gmail.com

Numerical experiment have been provided to estimate the number of principal components required to represent total delay signal in time series. It was done with the largest solid portion of the European data — 10400 values (433^d8^h) from 2002-01-17 00:30:00 to 2003-03-26 08:30:00 at the BOR1 station. Fig. 1 outlines the total dispersion of the series represented by principal components. In our previous work [4] it was shown that the series principal components, determined with SSA [2] might be subdivided into "noisy" and "deterministic" ones. In Fig. 1 the horizontal part of graph includes a lot of "noisy" principal components. That is why we subdivide the series of principal components by the position of turning point. It can be seen from Fig. 1 that three, or maybe four, principal components are sufficient for explanation of "deterministic" part of the series. Adding an extra components only enhances noise in the result.

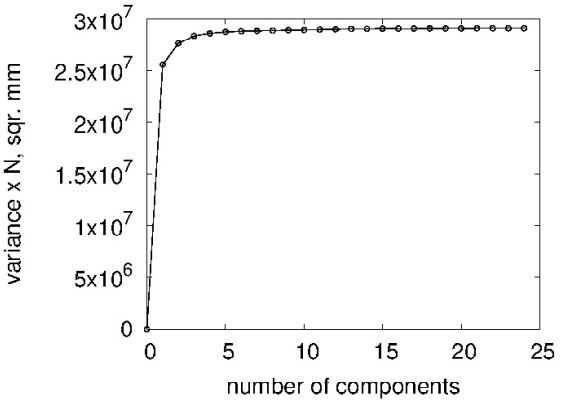

Fig. 1: Summary variance of first components

It should be noted that choosing different window sizes in SSA does not give any fundamentally new results for our testing – the SSA provides the same variance behaviour of this kind. Table 1 shows the estimated signal and noise variances. It is typical for all processed series.

Table 1: Variance analysis result of the example series.

Selection	Total variance, mm^2
Σ^2	2801
A	2729
B	2753
Ratio	Value
A/Σ^2	0.9743
B/Σ^2	0.9829

In Table 1 we present the total variation of the series, Σ^2, here A is variation of the first three principal components, B is the same for four components. It is clearly seen that three components are responsible for 0.9743 of total series variance. The remaining part of total variance is variance of the noise. Variation of the noise should be estimated as total variance minus given values. A and B are used in Table 2 in the same context. Fig. 2 visualises all series with solid, the first three (+) and the first four selections (×) with dotted line. TROTOT SD means standard deviation of measured value. These selections imitate the behaviour of the series decently. It is not possible to clearly define 4-th component as principal one, as it seen in Fig. 2 that selections behave very similar. Adding it does not change the behaviour of the principals.

GAP FILLING

Every gap in the data was interpreted as a place for internal forecasts. Left end of the gap is the starting point for forward forecast. The right end of the gap is the place where the backward forecast is applied. Those forecasts are moving to each other point by point and after all close the gap. It is obvious that the gap should not be wider than twice the size of the SSA window L. But sometimes the forecast works much better.

We have used common way to test forecasting capabilities, replacing real data by predicted ones. The he forecast with an example data from model section with gap size equals 72 ($3L$) is shown in Fig. 3. The prediction decently mimics the appearance of oscillations, but cannot handle with abrupt changes or outliers. These issues are discussed below.

Fig. 4 shows a gap in ALCI series of 48 points (2 days) – from 2003-12-07 00:30:00 to 2003-12-09 00:30:00 – perfectly filled in.

PREEDITING THE SERIES

Unfortunately sometimes is happens that the gap is filled wrong.

A marked dot (date: 2004-01-01 07:30:00) in Fig. 5 is an outlier. The LRF processing may lead to series' divergence. For this example forward forecast from left end of the gap looks OK, but backward one from right gap end diverges to abnormal negative values (not shown).

It may be proposed some explanation, for example, measuring device was broken, or after repairing it gave wrong results. Such values do not make practical sense because their probability is very small. That is why we applied sequential analysis to the original series near the gaps to exclude outliers [6]. The results are presented in Table 2 with 3σ rejection criterion.

FINAL RESULTS

Summarising all the remarks made it came up with the final results shown in Table 2. Location column separates the Ukrainian and European stations. Table 2 contains characteristics of each station, namely: its short name (name), location,

amount of provided measurements (points in total), amount of outliers, total variance on A, B and total selections (A, B, Σ^2 in mm^2), and its ratio.

We assume SSA works great in case of predicting of the series behaviour. It can be seen in Fig. 2. The sequential analysis makes good help to make prediction smoother, so it helps to minimise station's equipment random error. However, if TROTOT suffers abrupt changes, this changes are weakly reproduced in modelling, as it can be seen in Fig. 3. Theoretically, recurrent $T-th$ order forecast can be processed with sufficient precision $2T$ points forward. Practically, it works well for up to $10T$-sized gaps (SULP). Anyway if existing gaps are very wide (like in EVPA, GRAZ, ISTA, RIGA) the filling of the gaps with LRF fail.

CONCLUSIONS

We have used Singular Spectrum Analysis for TROTOT series processing. We find out that if $L = 24$, the first three or four principal components produce decent modelling of "deterministic" part of the series. On this basis we can fill gaps in series confidently. Also we assume total dispersion of "noisy" principal components evaluates quantity of noise in series decently.

The computation time of processing the SSA takes from several minutes up to 3–4 hours on the common laptop (`Eigen3` library (open-source, MPL2 license)[1], `C++`, Intel Core i3-5005, 4 cores), depending on series size ($\approx O(N^2)$).
